Chemistry Department University of Utah Salt Lake City, UT 84112

Abstract

Anionic states of Li3 were studied theoretically using a full-valence complete active space (CAS) self-consistent field (SCF) approach to explore their potential energy surfaces followed by quadratic configuration interaction (QCI) with single, double, and approximate triple excitations (SD(T)) calculations to more accurately determine relative energies and electron detachment energies. In addition to the known ${}^{1}\Sigma_{g}^{+}$ state, one triplet (${}^{3}A_{2}^{+}$) and two quintet (${}^{5}A_{1}^{+}$ " and ${}^{5}A_{2}^{+}$) states were found to be relatively low-lying and electronically and geometrically stable in D_{3h} geometries. All of these states remain electronically stable in C_{2v} and $D_{\infty h}$ geometries. Hence, they are amenable to photoelectron spectroscopy detection. Preliminary CAS SCF results for the valence isoelectronic Na3 are also reported.

I. Introduction

Alkali metal trimers may be considered as prototype clusters involving three monovalent s-orbital radicals. An excellent review on the neutral, cationic, and anionic alkali metal clusters has recently been published by Bonacic-Koutecky et al. [1]. Our interests in double-Rydberg anions [2] as well as in chemical bonds between Rydberg radicals [3] led us to this study on anionic states of the alkali metal trimers.

We recently studied several low lying doublet and quartet states of the neutral lithium trimer [4]. In addition to the well known pseudo-rotating ground state we considered excited electronic states which were recently explored using the two photon ionization technique [5,6]. Our results suggested a new assignment of the experimental peaks.

In this study we explore <u>anionic</u> states of the lithium and sodium trimers. Photodetachment spectra of the alkali metal trimers other than Li₃- were reported by Bowen's group a few years ago [7], whereas the spectrum of Li₃- has only recently been recorded [8]. The lithium clusters are difficult for experimental studies due to the high temperatures necessary to heat the metal and the corrosive properties of lithium [9].

Photoelectron spectra of all M_3 species (M=alkali metal atom) are dominated by two distinct and well separated peaks. These peaks are assigned to transitions beginning in the linear ${}^1\Sigma_g^+$ ($\sigma_g{}^2\sigma_u{}^2$) state of M_3 , with the resulting neutral species formed either in the ground ${}^2\Sigma_u^+$ ($\sigma_g{}^2\sigma_u{}^1$) or in the excited ${}^2\Sigma_g{}^+$ ($\sigma_g{}^1\sigma_u{}^2$) state.

For the ground ${}^2\Sigma_u^+$ state, the vertical detachment energy (VDE) is 1.309 ± 0.005 and 1.158 ± 0.010 eV, for Li₃- and Na₃-, respectively [7,8]. Upon bending, the ${}^2\Sigma_u^+$ state correlates with the lowest 2B_2 state (a local minimum on the pseudo-rotating ground state surface of the neutral). In earlier work, we indeed verified that linear Li₃ in the ${}^2\Sigma_u^+$ state is unstable with respect to the bending motion [4]. Hence, for the ${}^2\Sigma_u^+$ + e <-- ${}^1\Sigma_g^+$ transition, one can expect a difference between the VDE and adiabatic electron affinity (EA_a) equal roughly to the linearization energy of the ground state of M₃.

For the second ${}^2\Sigma_g{}^+ + e < {}^{-1}\Sigma_g{}^+$ transition, the experimental VDE is 2.003 ± 0.005 and 1.813 ± 0.010 eV, for Li₃- and Na₃-, respectively [7,8]. Our earlier work shows that the ${}^2\Sigma_g{}^+$ state is stable with respect to bending motion [4], hence the discrepancy between the VDE and EA_a is expected to be small for this transition.

Past theoretical studies on the anionic alkali metal trimers concentrated on the linear structure. Boustani and Koutecky found the ${}^{1}\Sigma_{g}^{+}$ state of Li₃- to be geometrically stable at the SCF level of theory, which was consistent with the electrostatic repulsion argument [10]. Electron detachment energies from the linear structures of Li₃- and Na₃- were studied by Ortiz using electron propagator theory [11] and by Bonacic-Koutecky et al. using the configuration interaction (CI) approach [12]. These theoretical results match the experimental data with an accuracy of 0.07 eV.

In the present work, we start from the monomers and dimers of the alkali metals to calibrate the accuracy of our calculations. The anions of M_2 are of particular interest. The photoelectron spectrum of Na_2 —was reported in Ref. [7], whereas that of Li_2 —has only recently been recorded [13]. Three observed electronic bands are assigned to transitions from the $X^2\Sigma_u^+$ ($\sigma_g^2\sigma_u$) bound state to $X^1\Sigma_g^+$ (σ_g^2), $a^3\Sigma_u^+$ ($\sigma_g\sigma_u$), and $A^1\Sigma_u^+$ ($\sigma_g\sigma_u$) states of M_2 . A Franck-Condon analysis of the lowest electron binding energy band allows one to determine spectroscopic constants of 7Li_2 —[13].

Our monomer and dimer calibration studies are followed by a thorough exploration of the singlet, triplet, and quintet states of Li_3 -for D_3 h, C_2 v, and D_∞ h geometries. To the best of our knowledge, the only other study in which a non-singlet anionic state was considered is that of Boustani and Koutecky [10]. They concluded that a linear stationary point of the lowest triplet state is not a minimum at the SCF level of theory, so they subsequently focused their attention on the linear singlet state.

In our study, the singlet, triplet, and quintet surfaces are explored at the full-valence complete active space (CAS) self consistent field (SCF) level of theory. More accurate relative energies and electron detachment energies are determined at the quadratic configuration interaction (QCI) level [14].

Presentation of our detailed results for Li3⁻ is followed by our preliminary results for Na3⁻. Guided by the lithium trimer results, we located stationary points on the full-valence CAS SCF potential energy surfaces of the neutral and anionic Na3, after which VDE's and EA_a's were determined at the same level of theory.

In addition to the lowest energy ${}^{1}\Sigma_{g}^{+}$ anionic state, we have found that a triangular ${}^{3}A_{2}^{+}$ ($a_{1}^{+}{}^{2}e^{+}{}^{2}$) state is electronically and geometrically stable for both alkali metal trimer anions. The electronic stability is preserved along a path from the D_{3h} minimum through C_{2v} structures to a linear local minimum (producing a ${}^{3}\Sigma_{u}^{+}$ state).

Another two previously unexplored triangular anionic states of 5A_1 " ($a_1'e^{i2}a_2$ ") and 5A_2 ' ($a_1'e^{i2}a_1$ ') symmetry were also found to be geometrically stable. They are also electronically stable with respect the lowest neutral quartet 4A_2 ' ($a_1'e^{i2}$) state. Hence, they are genuine bound states in the nonrelativistic approximation since they can not decay to lower lying (e.g., $X^1\Sigma_g^+$) anion states due to spin and orbital occupancy restrictions. The electronic stability of these quintet states is preserved along a C_{2v} path which connects the D_{3h} and $D_{\infty h}$ geometry. At linear geometry, these two quintet states correlate to a ${}^5\Pi_g$ ($\sigma_g{}^1\sigma_u{}^1\sigma_g{}^1\pi_u$) state. The 5A_1 " state preserves a positive curvature along the antisymmetric stretching mode in C_{2v} geometries, but the 5A_2 ' state (5B_2 in C_{2v}) is coupled through second-order Jahn-Teller interaction with another quintet 5A_1 state to yield negative curvature along the b_2 asymmetric stretch mode.

In Section II we discuss computational aspects of this study; Section III covers the anionic monomers and dimers, and in Section IV our results for the singlet, triplet, and quintet states of Li₃⁻ and Na₃⁻ are presented. In Section V we summarize.

II. Computational Aspects

The one-electron atomic basis sets for the lithium atom are detailed in Table I. The smaller one, labeled D, consists of Dunning's double-zeta (9s5p/3s2p) one-electron basis set [15] supplemented with diffuse s and p functions with the same exponent 0.0074 [16]

and one d function with the exponent 0.2 [17]. The larger basis set, labeled T, consists of Dunning's triple-zeta (12s6p/4s3p) set supplemented with the diffuse s and p functions [16] and two d functions with exponents 0.3 and 0.15. For the sodium atom we used the McLean and Chandler (12s9p/6s5p) set [18] supplemented with diffuse s and p functions with the same exponent 0.0076 [19] and one d polarization function with the exponent 0.175 [20].

The ground and excited potential energy surfaces for the neutral and anionic M₃ were studied at the CAS SCF level of theory. with the D basis set for Li3. The molecular orbitals derived from atomic core orbitals (1s for Li, 1s, 2s, and 2p for Na) were doubly occupied in every configuration state function (CSF). The resulting neglect of the core-core and core-valence correlation effects yields results we label <u>frozen core approximation</u> in subsequent discussion. These correlation effects are negligible for lithium and small for the sodium clusters due to low polarizability of the M⁺ cores [21]. The remaining three (neutral) or four (anion) electrons were distributed in all possible ways among the molecular orbitals derived from the atomic valence ns and np orbitals. This choice of the active space led to 572 and 220 CSF's for the doublet and quartet states of M3. For the anion, the number of CSF's is 1716, 2145, and 495 for singlet, triplet, and quintet states, respectively. The CAS SCF calculation for the dimer and the atomic species were performed with the analogous active spaces (i.e., frozen core approximation plus all valence orbitals in the active space).

The CAS SCF calculations were performed with the Utah MESS-KIT modular electronic structure codes [22] which generate the analytical second geometrical derivatives. Geometrical minima and transition states on the three-dimensional potential energy surfaces have been determined using our automated surface walking algorithm [23]. In cases where a small energy gap between electronic states of the same symmetry occurs, the CAS SCF wavefunction optimization for the higher state was performed in the state-averaged (SA) fashion [24], in which case only first analytical derivatives were available [25].

The full-valence CAS SCF method is sufficient to deliver detailed information about the potential energy surfaces. In particular it can deal with multiconfigurational problems. For ¹B₂ anionic state, however, the nature of a stationary point (minimum) determined at this CAS SCF level was counterintuitive. In particular, the curvature along the asymmetric stretching mode was questionable. In this dubious case, we also examined the results obtained using CAS active spaces smaller and larger than the full-valence space. These numerical tests strongly suggest that the ¹B₂ stationary point is a transition state rather than a minimum.

Due to the small number of valence electrons and the fullvalence active space, our CAS SCF electron detachment energies are quite accurate. For instance, the VDE's for Na₃- are off by at most 0.08 eV, for the two experimentally known transitions. Even more accurate detachment energies were determined for Li3- at the quadratic configuration interaction level with single, double, and approximate triple excitations (QCISD(T)) [14]. This method takes into account dynamical correlation effects and, due to its inherent sizeextensivity, it is well suited to deliver reliable electron detachment energies. Moreover, in our QCI calculations we removed the frozen core approximation so all core electrons were correlated. The OCISD(T) results were obtained with the Gaussian 92 suite of codes [26] using both the D and T basis sets. The difference in the electron detachment energies did not exceed 0.04 eV, thus, to conserve space, only the T basis set results are presented in later discussion. We expect that the reported detachment energies may be still in error by ca. 0.02 eV primarily due to: (i) inaccuracy of the geometrical parameters, (ii) neglect of f-symmetry basis functions.

Finally, the oscillator strength for the ${}^5A_2' < -- {}^5A_1"$ transition was calculated at the first-order configuration interaction (FOCI) level from the full-valence CAS reference space using the GAMESS package [27] and the D basis set.

III. Atoms and Dimers

Our CAS SCF and QCI separation between the atomic ²S and ²P states of Li is 1.84 eV. It compares well with the experimental data of 1.85 eV [28]. For Na, however, the CAS SCF ²S-²P separation is too low by 0.13 eV in comparison with the experimental value of 2.10 eV [28]. This larger discrepancy for Na is caused primarily by corevalence correlation effects which are neglected in our frozen-core approximation [12].

Our CAS SCF electron affinities for Li and Na are 0.52 and 0.47 eV, respectively, compared with the experimental data of 0.62 and 0.55 eV [29]. A full-CI calculation for the two outermost valence electrons, still with the frozen core approximation, leads to results of 0.59 and 0.54 eV. Finally, the QCI result for Li with the frozen core approximation released is 0.61 eV.

These results demonstrate that our full-valence CAS SCF approach and the D orbital basis set are capable of delivering reliable S-P energy separations between valence electronic states (accuracy ca. 0.15 eV) as well as meaningful electron affinities (low by ca. 0.1 eV). The inaccuracy of the CAS SCF VDE's is primarily caused by insufficient correlation between valence electrons. Refinement of the valence electronic states separations requires inclusion of corevalence and core-core correlation effects.

Our CAS SCF equilibrium internuclear distances, harmonic vibrational frequencies, and dissociation energies for the four lowest electronic states of Li₂ and Na₂ are reported in Table II. The agreement with other theoretical and experimental results is satisfactory. The discrepancies in equilibrium geometries do not exceed 0.1 au, with exception of the weakly bound $a^3\Sigma_u^+$ state where due to the shallow potential energy depth ($D_e \approx 0.02$ eV), a larger discrepancy (0.45 au) is reported for Na₂. The harmonic vibrational frequencies match the experimental/theoretical results to within 10 cm⁻¹ which is better than expected. The CAS SCF and QCI errors in D_o values do not exceed 0.12 eV and 0.04 eV, respectively. For the $^1\Sigma_u^+$ excited state the QCI result was unreliable, probably due to the

serious spin contamination at the UHF level. Only the CAS SCF results are reported for this state.

In Table II we also present CAS SCF spectroscopic parameters for Li₂ and Na₂. The agreement with the available experimental results for Li₂ [13] is excellent for R_e and ω_e , but D_o is off by 0.12 (CAS) and 0.04 eV (QCI).

In Table III we present VDE's and EAa's relative to the bound $^2\Sigma_u^+$ ground state of the anion. For the lowest VDE of Li2-, the agreement between our theoretical (QCI) and the experimental value is within 0.01 eV. The difference between the VDE and EAa is the smallest for the Li2($^1\Sigma_u^+$) + e <-- Li2- transition due to the similarity in equilibrium geometries of the neutral and the anion. The Li2($^3\Pi_u$) + e <-- Li2- transition was not (yet) observed experimentally [13], probably due to its two-electron (i.e., shake up) nature. The CAS SCF results systematically underestimate the VDE by ca. 0.1 eV in comparison with the experimental results.

IV. Trimers

Anionic sates of M_3 - have been explored in D_{3h} , C_{2v} , and $D_{\infty h}$ geometries. The dominant electronic configurations of the numerous low-energy anionic and neutral states can best be clarified using the molecular orbital correlation diagram for nsnp atoms shown in Fig. 1.

Several electronic states, (e.g., ${}^{1}\Sigma_{g}{}^{+}$, ${}^{3}A_{2}{}^{'}$, ${}^{5}A_{1}{}^{"}$, ${}^{5}A_{2}{}^{'}$) are electronically stable for a wide range of molecular geometries and are discussed in Sec. IV A. Many other states, such as ${}^{5}\Sigma_{g}{}^{+}$, ${}^{5}\Sigma_{u}{}^{-}$, ${}^{3}\Sigma_{g}{}^{+}$, ${}^{3}\Pi_{g}$, ${}^{1}A_{1}{}^{'}$, ${}^{25}A_{2}$, are electronically stable only for a limited range of molecular geometries. Certain of these, such as the ${}^{25}A_{2}$ state are promising candidates for long lived metastable states. Others, such as the ${}^{5}\Sigma_{g}{}^{+}$ state, cross the energy surface of the ground electronic state of the same multiplicity and thus have reduced lifetimes. All of these latter electronic states will be discussed in Sec. IV B.

The dominant electronic configurations, equilibrium geometries, harmonic vibrational frequencies, and relative energies are reported in Table IV for electronically stable (globally or locally) states of Li₃-. Calculated values of the VDE's and EA_a's for various

anion states are shown in Tables V and VI for Li3- and Na3-, respectively.

A. Globally Electronically Stable Sates

1. D_{3h} Geomucies and the C_{2v} Neighborhood

The lowest energy electronic configuration in D_{3h} geometry, $(2a_1'^22e'^2)$ produces the following electronic states: $1^3A_2'$, $1^1E'$, and $1^1A_1'$. All of these states are electronically stable with respect to the neutral $^2E'(2a_1'^22e')$. In addition, two quintet Li_3 -anionic states were found to be electronically stable with respect to the lowest quartet neutral state $^4A_2'(2a_1'^22e'^2)$. The latter are the $^5A_1''$ $(2a_1'^22e'^21a_2'')$ and $^5A_2'$ $(2a_1'^22e'^23a_1')$ states.

a. ³A₂' state.

This is the lowest energy anionic state in D_{3h} geometries. The CAS SCF equilibrium M-M separations are 5.93 and 7.09 au for Li₃ and Na₃, respectively. The Li₃ harmonic vibrational frequencies (187 (e') and 235 (a₁') cm⁻¹) indicate that this is a true minimum on the potential energy surface. For Li₃+ and Na₃+, our CAS SCF equilibrium M-M distances are 5.76 and 6.67 au, respectively, somewhat shorter than the anionic equilibrium geometries.

For Li₃-, the VDE corresponding to the transition ${}^2E' + e < -- {}^3A_2'$ is 0.761 eV at the QCI level and 0.679 eV at the CAS SCF level. Interestingly, the neutral M₃ thus produced would be in the neighborhood of the ${}^2E'$ conical intersection. Hence this triplet anionic state offers the experimental opportunity to prepare M₃ neutral clusters with initial geometries otherwise unavailable.

Since the ground state of the M_3 neutral is subject to first-order Jahn-Teller (FOJT) distortion, the value of EA_a differs from VDE by at least the FOJT stabilization energy ($^2E'$ --> 2B_2). In fact, the QCI difference is 0.134 eV, whereas our stabilization energy is only 0.065 eV.

The QCI VDE for the ${}^4A_2{}^{'}$ ($a_1{}^{'}e^{'2}$) + e <-- ${}^3A_2{}^{'}$ transition is 1.755 eV for Li3⁻. The resulting neutral ${}^4A_2{}^{'}$ is the lowest energy quartet for D_{3h} geometries. The difference between this VDE and EA_a is predicted to be small since the ${}^4A_2{}^{'}$ neutral is also geometrically stable at D_{3h} geometries with an equilibrium M-M distance of 6.01 au.

It is worth noting that our electron detachment energies from the 3A_2 ' state discussed above (0.761 and 1.755 eV) differ from the experimental peaks at 1.309 and 2.003 eV [8] which derive from the linear singlet form of Li₃-. This makes detection of the 3A_2 ' anion plausible, providing a significant concentration of the triplet isomer can be produced in the anionic beam.

For today, there is no experimental evidence for the ³A₂' state of the alkali metal trimers. However, an unidentified excited electronic state of Cu₃- was observed by Leopold et al. in photoelectron spectroscopy experiments using 2.540 and 2.707 eV photons [30]. The strong peak with VDE of 2.35-2.55 eV, assigned to a linear structure, was accompanied by a feature which is more than two orders of magnitude weaker and possesses a VDE of ca. 1.5 eV. It was verified that the weak feature is due neither to a copper oxide (e.g., Cu₂O₄-) nor to a copper cluster containing any other foreign species [30]. Thus the authors of Ref. [30] assigned the weak band to an electronically excited state of Cu₃-. Of course, the peaks observed for Cu₃- have much higher VDE's than those for the alkali metal trimers, consistent with the difference in the bulk work functions. Hence, it may well be that the ³A₂' state of Cu₃- was observed by Leopold et al. [30].

b) ¹E' state

The state $1^1E'$ is subject to FOJT distortion which lowers the molecular symmetry to $C_{2\nu}$ and produces two distinct electronic states

 $1^{1}A_{1}$: $c_{1}3a_{1}^{2}2b_{2}^{2}$ - $c_{2}3a_{1}^{2}4a_{1}^{2}$

 $1^{1}E'$ ($1^{1}B_{2}: 3a_{1}^{2}4a_{1}2b_{2}$

with the 1^1A_1 and 1^1B_2 states favoring obtuse and acute triangle, respectively. The coefficients c_1 and c_2 are equal in D_{3h} geometries, but not at the distorted structures.

The 1^1A_1 state correlates with the lowest energy linear $^1\Sigma_g^+$ isomer of M_3^- and no barrier was observed along this rearrangement path. As M_3^- approaches the linear structure, the role of the $3a_1^24a_1^2$ configuration decreases (i.e., the absolute value of the c_2 coefficient uniformly decreases).

For the 1¹B₂ offspring of the 1¹E' state the full valence CAS SCF geometry optimization led to a stationary point with R=6.193 au and an angle of 55.19°. The harmonic frequencies of all normal modes are real (see the seventh row in Table VII) which initially led us to conclude that another electronically stable minimum for M₃- had been found.

However, when we performed additional CAS SCF calculations with active spaces smaller and larger than the full-valence space, the harmonic frequencies reported in Table VII were obtained. The frequencies for the symmetric stretching and bending modes are stable within 35 cm⁻¹. The asymmetric stretching mode frequency is imaginary for small CAS spaces, real for the full-valence, and again imaginary for the largest CAS space considered. Clearly, the full-valence CAS SCF prediction as to the nature of the ¹B₂ stationary point seems to be misleading. This is an annoying artifact of non-full CI calculations.

The behavior of the b₂ mode frequency as a function of calculation quality must be related to symmetry-breaking [31]. Previous numerical observations indicated that this may happen in single-configurational calculations in which some correlation effects could be included in the wavefunction at the expense of incorporating extra configurations of the wrong symmetry. A remedy against this artifact was to include in the configuration space all important configurations of the correct symmetry. Here, however,

we report anomalies at the full-valence CAS SCF level which is believed to be satisfactory in chemical applications, though computationally demanding. On the other hand, the b₂ mode frequencies are consistently imaginary in small valence spaces. The reported results indicate that the anionic ¹B₂ stationary point is actually a transition state.

The origin of the b_2 frequency instability definitely requires further investigations. Our preliminary results indicate that the full-valence CAS SCF energy is very flat with respect to the $a_1 < --> b_2$ orbital rotations. This may affect the stability of the solutions of the coupled-MCSCF equations for the first-order geometrical responses. The flatness of the full-valence energy is probably related to the very small number of valence electrons in the case of alkali metal clusters.

The three equivalent 1B_2 transition states connect three equivalent linear ground state structures of $^1\Sigma_g^+$ symmetry, with the reaction path going through C_s geometries. The graph representing this nonrigid intramolecular rearrangement is shown in Fig. 2. The initial distortion from the linear structure involves the motion along the bending (π_u) and antisymmetric stretching (σ_u) modes, whereas that from the $C_{2\nu}$ structure is primarily along the antisymmetric stretching b₂ mode. The energy barrier for the rearrangement is 0.68 eV at the CAS SCF level of theory. The QCI approach is inapplicable for the 1B_2 state, similarly as for the $^1\Sigma_u^+$ state of the dimer.

c) ⁵A₁" state

This anionic state may by characterized as the lowest energy quartet state of the neutral (i.e., ${}^4A_2{}^{\prime}$ ($2a_1{}^{\prime}2e^{\prime}{}^2$)) with an extra, highspin coupled electron in the $1a_2{}^{\prime\prime}$ orbital whose electronic density is distributed above and below the molecular plane. Hence, it does not significantly disturb the bonding of neutral ${}^4A_2{}^{\prime}$, for which the electron density is accommodated primarily in molecular plane.

Indeed, the equilibrium R for this 5A_1 " state (5.80 au) is even smaller than that of the 4A_2 ' neutral, which is 6.01 au, probably due to the constructive interaction among the np AO's in the 1a_2 " MO. The

similarity between the neutral 4A_2 ' and the anion 5A_1 " manifests also in the CAS SCF harmonic frequencies which are 187 (e') and 221 (a₁') for 5A_1 " and 189 (e') and 218 (a₁') for 4A_2 '.

In the nonrelativistic approximation, the 5A_1 " state is a genuine bound state. The VDE to the lowest neutral 4A_2 ' state is 0.56 eV which is even lower than EA_a values for the ${}^2B_2 + e < -- {}^3A_2$ ' transition. Therefore, the 5A_1 " state may also be amenable to photoelectron spectroscopy detection.

d) ⁵A₂' state

This state may be characterized as the neutral 4A_2 ' with an extra high-spin coupled electron, this time in the $3a_1$ ' orbital. The extra electron density is in the molecular plane, so larger differences are expected between the neutral and the anion, than those reported above for the 5A_1 " ion.

Indeed, despite the bonding properties of the $3a_1$ ' orbital, the equilibrium internuclear distance in 5A_2 ' is larger by 0.3 au than in the neutral 4A_2 ' and the vibrational frequencies for the 5A_2 ' state are 130 (e') and 184 (a₁'), thus smaller than those for the 4A_2 ' neutral.

In the nonrelativistic approximation, the ${}^5A_2{}'$ anion is another bound electronic state. The transition ${}^5A_2{}' < -- {}^5A_1{}''$ has a vertical excitation energy of 994 cm⁻¹ (QCI) or 1178 cm⁻¹ (FOCI) and the oscillator strength 0.013 (FOCI). This prediction should help in future experimental search for anionic quintet states.

The extra electron is less bound in this 5A_2 ' state than in the 5A_1 " state. For Li₃- the value of the 5A_2 ' VDE is 0.29 (CAS) and 0.47 (QCI). For Na₃-, the VDE value of 0.12 eV (CAS) is even smaller.

The ${}^5A_2{}'$ state correlates with a higher in energy ${}^5\Pi_g$ linear state, as the ${}^5A_1{}''$ state does. Both ${}^5A_2{}'$ and ${}^5A_1{}''$ states may be considered as molecular analogs of the core-excited atomic anionic states studied by Bunge and collaborators [32].

2. D_{∞h} Geometries and the C_{2v} Neighborhood

a) ${}^{1}\Sigma_{g}^{+}$ state

This is the lowest energy isomer of M_3 . The CI wavefunction is dominated by the configuration $3\sigma_g^2 2\sigma_u^2$ and the $2\sigma_u$ orbital displays an antibonding interaction between the terminal Li atoms; hence the nature of the doubly occupied $2\sigma_u$ orbital helps preserve linear structure. The same effect may cause the equilibrium M-M distance to be larger (by 0.24 au) than in the ground state linear neutral $2\Sigma_u^+$ ($3\sigma_g^2 2\sigma_u$).

The latter state, however, is geometrically unstable with respect to bending motion since the effect of the singly occupied $2\sigma_u$ orbital is apparently overweighed by the preference of the doubly occupied $3\sigma_g$ orbital for D_{3h} geometry. The $^2\Sigma_u$ + state correlates with the 2B_2 state which has a minimum at R=5.34 au and an angle of 72.63° .

The VDE of the ${}^2\Sigma_u^+ + e < {}^{-1}\Sigma_g^+$ transition is 1.322 eV and the EA_a is smaller by 0.317 eV, whereas the linearization energy for 2B_2 neutral is 0.289 eV. Due to significant difference between the anionic and neutral equilibrium structure, the photodetachment peak is expected to display a significant Franck-Condon width.

Another neutral state that is related to the ${}^{1}\Sigma_{g}{}^{+}$ anion through a single electron process is the ${}^{2}\Sigma_{g}{}^{+}$ state, with the dominant configuration $3\sigma_{g}2\sigma_{u}{}^{2}$. This electronic configuration suggests a linear equilibrium structure and a bond length even longer than in the ${}^{1}\Sigma_{g}{}^{+}$ anion. This is indeed the case as the equilibrium R for ${}^{2}\Sigma_{g}{}^{+}$ is 5.96 au.

The photodetachment peak related to the ${}^2\Sigma_g{}^+ + e < {}^{-1}\Sigma_g{}^+$ transition has a VDE of 1.992 eV. Since there is small relaxation in the neutral equilibrium geometry, the EA_a of 1.995 eV is quite similar to VDE, so the peak is expected to be sharp.

Our theoretical results are in a good agreement with the experimental data which predict VDE's of 1.309 \pm 0.005 eV (wide peak) and 2.003 \pm 0.005 eV (sharp peak) for transitions leading to $^2\Sigma_u^+$ and $^2\Sigma_g^+$ products, respectively [8].

b) $^3\Sigma_u^+$ state

The dominant configuration of this state is $3\sigma_g^2 2\sigma_u^4 \sigma_g$ which correlates with the D_{3h} $^{3}A_{2}$ state. Since the orbital energies of $2\sigma_{u}$ and $4\sigma_g$ have opposite dependence on bending angle, the surface of the ${}^{3}\Sigma_{u}^{+}$ state is expected to be quite flat with respect to bending. In fact, our bending frequencies are only 53 cm⁻¹ at both the CAS SCF and MP2 levels. Since they are real, a transition state is anticipated when a $D_{\infty h}$ structure is approached from the D_{3h} minimum. We actually performed a transition state search and found one at an angle of 1420 and R=5.95 au., with an energy higher by 0.271 eV (CAS) than at the D_{3h} minimum, and an imaginary frequency of 34 cm⁻¹. This transition state was, however, 0.002 eV lower than the linear ${}^{3}\Sigma_{u}^{+}$ minimum. Approaching the linear structure, another C_{2v} minimum was found at R=5.99 au and an angle of 1690 with an energy only 0.002 eV below the transition state and a real bending frequency of 23 cm⁻¹. We abandoned looking for other transition states since the energy changes involved are below the accuracy of our CAS SCF approach. The most reasonable conclusion to draw is that the surface is actually very flat with respect to the bending motion. Interestingly, the optimal distance R remains within the range of 5.9-6.0 au for all the stationary points found.

The $^3\Sigma_u^+$ state is electronically stable for linear geometries, and the value of EA_a for the transition leading to the lowest energy $^2\Sigma_u^+$ neutral is still 0.589 eV. We thus conclude that the lowest triplet anionic state is electronically stable for D_{3h} , C_{2v} , and $D_{\infty h}$ geometries.

c) $^{5}\Pi_{g}$ state

The dominant configuration of this state is $3\sigma_g 2\sigma_u 4\sigma_g 1\pi_u$. Despite simple molecular orbital arguments, see Fig. 1, and the fact that this state correlates with the two lowest D_{3h} 5A_1 " and 5A_2 ' states, the $^5\Pi_g$ state lies above the $^5\Sigma_g$ + $(3\sigma_g 2\sigma_u 4\sigma_g 3\sigma_u)$ state by 0.117 eV. The lower $^5\Sigma_g$ + state, which is electronically stable only in the neighborhood of the linear structure, will be discussed in Sec. IVB.

The CAS SCF frequencies for the $^5\Pi_g$ state indicate that the Renner-Teller splitting for the bending modes is less than 0.5 cm⁻¹.

The fact that both such frequencies are real indicates that the 5A_1 " (5A_2) and 5A_2 ' (5B_2) states correlate to the ${}^5\Pi_g$ state through transition states. Our searches for these transition states started at D_{3h} geometries and moved uphill along the bending mode. Stationary points at R=6.02 au, angle 126.8°, v_{bend}= 57i cm⁻¹ and R=6.07 au, angle 131.4°, v_{bend}= 47i cm⁻¹ were found for the 5A_2 and 5B_2 states, respectively. The energies of these transition states are 0.02 eV below (5A_2) and 0.01 eV above (5B_2) the energy of the ${}^5\Pi_g$ minimum. Clearly, the surfaces become very flat from the angle of ca. 120°; for this reason we did not pursue further study for C_{2v} geometries closer to the linear structure since the accuracy of our CAS SCF data would be not sufficient. The flatness of the 5A_2 and 5B_2 surfaces is probably related to the opposite angular dependence of the 2b₂ and 4a₁ orbital energies, see Fig. 1.

The fact that the ${}^5\Sigma_g{}^+$ state is lower than the ${}^5\Pi_g{}$ state at linear geometries indicates that, in a $C_{2\nu}$ geometry, there is a crossing between the ${}^5A_1{}({}^5\Sigma_g{}^+)$ and the ${}^5B_2{}$ component of the ${}^5\Pi_g{}$ state. In this region, the ${}^5B_2{}$ state becomes geometrically unstable with respect to the $b_2{}$ vibrational mode due to second-order Jahn-Teller coupling [33]. In addition, "hopping" to the ${}^5A_1{}({}^5\Sigma_g{}^+)$ surface can take place. Both factors will decrease the lifetime of the ${}^5A_2{}'$ state, in addition to the radiative decay channel.

The electronic stability of the ${}^5\Pi_g$ state has to be considered with respect to two low-energy neutral quartet states, ${}^4\Sigma_u{}^+$ ($3\sigma_g 2\sigma_u 4\sigma_g$) and ${}^4\Pi_g$ ($3\sigma_g 2\sigma_u 1\pi_u$). The equilibrium geometries of the former (R=7.47 au) and the latter (R=5.41 au) differ significantly from the equilibrium R of ${}^5\Pi_g$, which is 6.08 au. Hence, a major difference is expected between the corresponding VDE and EA_a energies: VDE=0.656 and 0.783 eV, EA_a = 0.603 and 0.640 eV for the ${}^4\Sigma_u{}^+$ and ${}^4\Pi_g$ transitions, respectively.

We conclude that the 5A_1 " and 5A_2 ' quintet anionic states are electronically stable in D_{3h} , C_{2v} , and $D_{\infty h}$ geometries.

- B. Locally Electronically Stable Species
- a) 1¹A₁' state

This state results from the same $2a_1'^22e'^2$ configuration that produces the $^1E'$ and $^3A_2'$ states. Even though this state is not subject to FOJT distortion, we write its approximate CI wavefunction $c_1 3a_1^2 2b_2^2 + c_2 3a_1^2 4a_1^2$ in the C_{2v} orbital symmetry notation to make the difference between $1^1E'$ and $1^1A_1'$ transparent.

The geometry of this state was optimized within D_{3h} symmetry and the geometrical hessian analysis indicates that this is a minimum structure indeed, see Table IV. The anion is electronically stable with respect to the lowest $^2E'$ ($2a_1'^22e'$) state of the neutral by 0.065 eV (CAS level).

Recall that the ${}^2E'$ state of the neutral is FOJT unstable and we found that the 2B_2 minimum of Li₃ is lower by 0.058 eV (CAS) than the D_{3h} ${}^1A_1'$ minimum of Li₃. Clearly, the anionic and neutral surfaces must cross in C_{2v} symmetry not far from the D_{3h} manifold. The electronic stability of the anion is thus restricted to a small part of the potential energy surface so this state cannot be long lived.

b) ${}^3\Sigma_g$ + state

This is a state with two important configurations: $3\sigma_g 2\sigma_u^2 4\sigma_g$ and $3\sigma_g^2 2\sigma_u 3\sigma_u$. Its minimum energy geometry was found at R=6.04 au where the bending mode frequency is only 86 cm⁻¹. Hence, C_{2v} geometries are easily accessible. This state correlates at D_{3h} geometries to an electronically unstable $^3E'$ state. Therefore, the electronic stability is restricted to linear geometries and their close neighborhood; at linear geometry, the state is electronically stable with respect to the lowest neutral $^2\Sigma_u^+$ state by 0.340 eV (EA_a).

c) $^3\Pi_g$ state

For this anionic state, the dominant configuration is $3\sigma_g^2 2\sigma_u 3\pi_u$. A geometry minimum was found at R=5.53 au with a Renner-Teller splitting of 7 cm⁻¹. The bending frequencies are low, hence $C_{2\nu}$ geometries are easily accessible. The 3B_2 component of this

 $^3\Pi_g$ state correlates with the same D_{3h} $^3E'$ state as the $^3\Sigma_g^+$ state does. The 3A_2 component of this state correlates with an electronically unstable $^3E''$ state. Therefore, the electronic stability of the $^3\Pi_g$ state is restricted to linear geometries and their close neighborhood where it is stable with respect to the lowest neutral $^2\Sigma_u^+$ state by 0.173 eV (EA_a).

d) $5\Sigma_g$ + state

This is the lowest energy quintet state at linear geometries and has a dominant configuration $3\sigma_g 2\sigma_u 4\sigma_g 3\sigma_u$. Due to the counterbalancing energy dependence of the $2\sigma_u$ and $4\sigma_g$ orbitals, the surface is expected to be flat with respect to bending. In fact, the bending frequency is only 76 cm⁻¹ and $C_{2\nu}$ geometries are easily accessible.

In D_{3h} symmetry, this state correlates with the ${}^5E'$ ($2a_1'2e'^23e'$) state which is electronically unstable. Hence, the electronic stability of the ${}^5\Sigma_g^+$ state is restricted to linear geometries and their close neighborhood, where a crossing with the 5B_2 (${}^5A_2'$) state takes place, accompanied by second-order Jahn-Teller instability and possibility of surface "hopping".

At linear geometries, the ${}^5\Sigma_g{}^+$ state is electronically stable with respect to the two lowest quartet states of the neutral: VDE=0.726 eV and 1.073 eV, EA_a=0.720 eV and 0.756 eV, for the ${}^4\Sigma_u{}^+$ and ${}^4\Pi_g$ state, respectively.

e) ⁵E" state

The ⁵E" state is a candidate for a long-lived, metastable, pseudo-rotating state. The electronic stability of this state is discussed below, for different regions of the potential energy surface.

In D_{3h} geometries, the 5E " $(2a_1'2e'1a_2"3a_1')$ state is electronically unstable with respect to the ground quartet ${}^4A_2'$ $(2a_1'2e'^2)$ state. However, since the $2a_1'2e'1a_2"3a_1'$ configuration differs from the $2a_1'2e'^2ke$ " configuration needed to produce the ${}^4A_2'$ neutral (ke" denotes an e" symmetry orbital for the outgoing

electron) by two spinorbital occupancies, the coupling to this detachment channel is expected to be weak. Among configurations which contribute to 5E " and simultaneously can couple to the 4A_2 ' neutral in a one-electron process, the largest CI coefficient (only 0.12) was found for the $2a_1$ '2e'21e" configuration. The neutral state 4E " ($2a_1$ '2e' $1a_2$ "), to which the anion could couple in a one-electron process, is higher in energy than the anion by 0.23 eV (CAS level at the cation equilibrium geometry).

The ⁵E" state is FOJT unstable, producing 2⁵A₂ and 1⁵B₁ states which favor obtuse and acute structures, respectively, consistent with the bending angular dependence of the 4a₁ and 2b₂ orbitals. A stationary point on the ⁵B₁ (3a₁4a₁1b₁5a₁) surface, with R=6.44 au and an angle of 43.6°, proved to be a transition state, with a negative curvature along the asymmetric stretching mode, see Table IV. At this geometry, the energy of the ⁵B₁ state is lower than the energy of the lowest quartet ⁴B₂ neutral state by 0.04 eV (CAS) and 0.22 eV (QCI). Hence, the electronic instability of the anionic quintet state is probably restricted to D_{3h} geometries and the close neighborhood.

Geometry optimization for the 2^5A_2 offspring of the 5E " state was performed in the state-averaged CAS SCF procedure, to avoid "root-flipping" [34]. Three electronic states were state-averaged with equal weighting factors: 1^5A_2 (5A_1 "), 1^5B_2 (5A_2 '), and 2^5A_2 (5E "), and the CI mixing was significant between two 5A_2 $3a_12b_24a_11b_1$ and $3a_12b_21b_15a_1$ configurations.

A stationary point for the 2^5A_2 state was found at R=5.28 au, and an angle of 111.5°. We expect it is a minimum, but the finite difference hessian formed in the SA CAS SCF C_{2v} optimization does not allow us to determine the b_2 mode frequency. Interestingly, at this stationary point, the energy of the lowest 4B_2 neutral state calculated without the SA constraint is higher by 0.14 eV than the energy of the SA optimized 2^5A_2 anion. This indicates that the 2^5A_2 state is electronically stable at the stationary point.

Determination of the pseudo rotation barrier on the 5E " surface requires a consistent calculation of the 1^5B_1 and 2^5A_2 energies. Hence, we recalculated the energy of 1^5B_1 at its stationary point using the SA procedure involving 1^5A_2 , 1^5B_2 , and 1^5B_1 states. The

resulting energy was only 0.07 eV higher than the single-state CAS SCF energy and the pseudo rotation barrier is estimated to be 544 cm⁻¹.

The 2^5A_2 state correlates with the linear ${}^5\Sigma_u^-$ ($3\sigma_g 2\sigma_u 1\pi_u ^2$) state. This i the third electronically stable anionic quintet state at the linear geometry, and is higher in energy than the ${}^5\Sigma_g ^+$ and ${}^5\Pi_g$ states by 0.341 and 0.225 eV (QCI), respectively. A stationary point was found for the ${}^5\Sigma_u ^-$ state at R=5.29 au, with a bending frequency of only 56 cm⁻¹. The anion is electronically stable with respect to the two lowest quartet states of the neutral: VDE=0.678 and 0.410 eV, EA_a = 0.379 and 0.415 eV, for ${}^4\Sigma_u ^+$ and ${}^4\Pi_g$, respectively.

V. Summary

The alkali metal trimer anions possess more than one electronically and geometrically bound state. In addition to the known ${}^{1}\Sigma_{g}^{+}$ state, one triplet ${}^{3}A_{2}^{'}$ and two quintet ${}^{5}A_{1}^{"}$, ${}^{5}A_{2}^{'}$ states are predicted to be electronically stable for a wide variety of geometries. The multitude of electronically bound states is probably related to the small energy separation between valence ns and np atomic orbitals in alkali metal atoms.

The linear ${}^{1}\Sigma_{g}^{+}$ $(3\sigma_{g}^{2}2\sigma_{u}^{2})$ state is the lowest energy isomer of Li₃. Our VDE for the ${}^{2}\Sigma_{u}^{+}$ + e <-- ${}^{1}\Sigma_{g}^{+}$ and ${}^{2}\Sigma_{g}^{+}$ + e <-- ${}^{1}\Sigma_{g}^{+}$ transitions are 1.322 and 1.995 eV, respectively, in good agreement with the experimentally observed peaks at 1.309 \pm 0.005 and 2.003 \pm 0.005 eV [8]. The barrier for nonrigid intramolecular rearrangement of the linear isomer was found to be 0.68 eV and to pass through a C_{2v} symmetry ${}^{1}B_{2}$ transition state.

The 3A_2 ' $(a_1'^2e'^2)$ anion is the lowest energy isomer in D_{3h} geometries. This triplet state remains electronically stable in C_{2v} and $D_{\infty h}$ geometries. Our VDE for the ${}^2E' + e < {}^{-3}A_2'$ and ${}^4A_2' + e < {}^{-3}A_2'$ transitions in Li₃ are 0.761 and 1.755 eV, respectively. Hence, the peaks should be clearly distinct from the transitions involving the linear ${}^1\Sigma_g^+$ anion, thereby suggesting further experimental study.

After this work was completed, we were pleased to find that Bauschlicher et al. [35] also invoked the ³A₂' anionic state to explain

the weak feature in the photoelectron spectrum of Cu₃- [30] and found a VDE for the triplet D_{3h} isomer of Cu₃-, calculated at the modified coupled pair functional level of theory, in good agreement with the experimental finding. Interestingly, the weak feature ascribed to the ³A₂' anion was not observed in the later work from the Lineberger group [36], presumably due to cooler ion source conditions.

Two quintet 5A_1 " and 5A_2 ' anionic states were also identified that may be thought of as the lowest energy quartet 4A_2 ' $(a_1'e'^2)$ state of the neutral with an extra high-spin coupled electron attached to a a_2 " or a_1 ' orbital, respectively. These quintet states are genuine bound states in the nonrelativistic approximation, and may be considered as molecular analogs of core-excited atomic anionic states studied earlier [32]. The vertical excitation energy for the radiative 5A_2 ' <-- 5A_1 " transition is ca. 1000 cm⁻¹ and the oscillator strength is 0.013.

For the 5A_1 " and 5A_2 ' states of Li3-, the vertical detachment energies to the 4A_2 ' state neutral are 0.563 and 0.465 eV, respectively. Both quintet states remain electronically stable with respect to the lowest neutral quartet state along a bending motion path to the linear structure, where they correlate with a ${}^5\Pi_g$ state. When proceeding to the linear structure, the 5A_2 ' (5B_2) state intersects with the ${}^5\Sigma_g$ + (5A_1) state, so geometrical instability must develop along the b_2 mode and surface "hopping" may take place.

The lithium trimer also possesses many anionic states which are electronically stable for restricted geometries only. The most interesting of them is probably the pseudo-rotating 5E " state. It is electronically unstable in D_{3h} geometries, but stable at the stationary points of the 5B_1 (transition state) and 5A_2 (minimum) surfaces. Moreover, the 5E " wavefunction displays properties required to be classified as a Feshbach resonance state at D_{3h} geometries.

An extension of our present conclusions to other alkali metal trimers would be important. It is encouraging that our preliminary CAS SCF results for Na₃- are qualitatively the same as those for Li₃-. The presence of alkali metal atoms in heteroatomic radicals may enhance an ability to form more than one electronically bound

anionic state. Indeed, the whole family of lithium substituted double-Rydberg anions accommodates an excited triplet state in addition to the ground fully-symmetric singlet state [37].
